The stabilised orthorhombic perovskite  $\text{Ba}_2\text{In}_{1.8}\text{S}_{0.2}\text{O}_{5.3}$  was synthesised by solid state reaction at low-temperature. The mixed (electronic-protonic-oxide-ionic) conducting properties of this composition were investigated in detail for potential interest in a wide range of membrane applications including Protonic Ceramic Fuel Cells. The electrochemical analyses performed include impedance spectroscopy in wet/dry conditions of  $\text{N}_2$  and  $\text{O}_2$  and modified electromotive force measurements in wet/dry mixtures of  $\text{N}_2/\text{O}_2$ . In dry oxidising conditions the sample possesses mixed electronic-oxide-ionic contributions to the electrical transport in the whole range of temperature, associated with the equilibrium between oxygen vacancies and holes. In wet atmospheres, protonic species arise from the hydration reaction. Protons represent the dominant charge carriers for temperatures lower than 550 °C, while oxide-ions and holes are the major mobile species for temperatures higher than 700 °C. Appreciable mixed contributions to the electrical transport from protons, oxide ions and holes are confirmed between 550-700 °C. The experimental data obtained from modified electromotive force measurements and impedance spectroscopy fit well with the expected results according to the proposed defect chemistry model.

## 1. Introduction

The search for ionic (both protonic and oxide-ionic) conductors with energy technological applications have attracted great attention due to their potential use as humidity and/or hydrogen/oxygen sensors, oxygen pumps, selective membranes and electrolytes in intermediate and high temperature solid oxide fuel cells (SOFCs)<sup>1-4</sup>. The present state-of-the-art, reference materials are those operating at high temperatures, mainly with fluorite-type structures (for example, CaO- or  $\text{Y}_2\text{O}_3$ -doped  $\text{ZrO}_2$ ). Nonetheless, for operational use in devices of commercial relevance, restriction to temperatures below 600 °C has been suggested, due to enhanced cell longevity and reduced cost of balance of plant<sup>5, 6</sup>. The search for alternative materials that offer higher ionic conductivities at lower temperatures has, thus, become a highly active area of research to facilitate this transition. Perovskite-type and crystallographically related materials can offer this opportunity as they tolerate high compositional flexibility that permits the tailoring of properties by manipulation of defect chemistry.

In this context,  $\text{Ba}_2\text{In}_2\text{O}_5$  was recognized to exhibit high

oxide- and protonic-ion conductivity at elevated and intermediate temperatures, respectively<sup>7-11</sup>. The  $\text{Ba}_2\text{In}_2\text{O}_5$  brownmillerite structure ( $\text{A}_2\text{B}_2\text{O}_5$ ) can be described as a common perovskite ( $\text{ABO}_3$ ) with 1/6 of oxygen vacancies sited along the direction of an orthorhombic symmetry<sup>9</sup>; resulting in ordered alternating sheets of  $[\text{BO}_6]$  octahedra and  $[\text{BO}_4]$  tetrahedra. At high temperature ( $\approx 925$  °C), oxygen vacancies become randomly distributed leading to phase transition to cubic perovskite symmetry with high ionic conductivity<sup>7, 12, 13</sup>. In addition, a new and reversible phase transition from the  $\alpha$ -form,  $\text{Ba}_2\text{In}_2\text{O}_5$ , to the  $\beta$ -phase,  $\text{Ba}_2\text{In}_2\text{O}_5 \cdot \text{H}_2\text{O}$  (tetragonal symmetry,  $P4/mmm$ ), was reported at temperatures around 300 °C, under wet atmospheres. Although the  $\beta$ -phase is considered an excellent proton conductor, its use in electrochemical devices could not be recommended, due to substantial volume changes during the phase transition<sup>12, 14, 15</sup>.

Following the objective to enhance the chemical and structural stability as well as the conductivity of  $\text{Ba}_2\text{In}_2\text{O}_5$  at fuel cell operating conditions, several recent works proposed alternative dopant substitutions, either in the A-, B-site or both sites simultaneously. The main objective is to stabilize the high temperature phase, of oxygen vacancy disorder, to lower temperatures to promote high levels of proton or oxide-ion conductivity.  $\text{Sr}^{2+}$  substitution at the A-site was found to increase the order-disorder temperature transition ( $T_d$ ) whereas  $\text{Ga}^{3+}$  substitution at B-site was shown to decrease it<sup>16, 17</sup>. The addition of lanthanum in  $\text{Ba}_{2-x}\text{La}_x\text{In}_2\text{O}_5$  lowered  $T_d$  until the disordered high temperature phase was finally stabilised to room temperature in compositions with values of

## Journal Name

$x > 0.1$ <sup>18, 19</sup>. Examples of B-site aliovalent substitution can also be found. Substitution of  $\text{In}^{3+}$  by rare earth elements,  $\text{Ba}_2\text{In}_{2-x}\text{R}_x\text{O}_5$  (being  $\text{R} = \text{Sc}, \text{Lu}, \text{Yb}, \text{Gd}, \text{Sm}$ )<sup>20, 21</sup> produced a  $T_d$  temperature decrease for cations smaller than indium related to their preferential occupation of the tetrahedral  $[\text{InO}_4]$  sites instead of the octahedral positions<sup>22</sup>. B-site substitutions with Ce were shown to yield a proton conductor with significant conductivity in the 100–300 °C temperature range, generating a potential candidate even for fuel cells operating at very low temperatures<sup>23</sup>. More recently, new doping strategies based on oxyanion substitutions in B-site have attracted attention.  $\text{SO}_4^{2-}$ ,  $\text{PO}_4^{3-}$  or  $\text{SiO}_4^{4-}$  anion<sup>24–27</sup> doping in the B-site favour anionic disorder and simultaneously increase the oxide-ion conductivity at lower temperatures and proton conductivity under humid conditions.

In the framework of such oxyanion doping, the present work explores the perovskite composition  $\text{Ba}_2\text{In}_{1.8}\text{S}_{0.2}\text{O}_{5.6}$  obtained by the solid-state method. The formation of a single phase composition is verified by X-ray diffraction (XRD). Impedance spectroscopy (IS) is used to determine the electrical conductivity under different gas atmospheres. Moreover, more detailed conduction characteristics are analyzed by electromotive force (EMF) measurements under both dry and wet conditions. The contribution of either protonic- oxide-ionic and hole charge carriers to the total transport phenomenon at different  $p\text{O}_2$ ,  $p\text{H}_2\text{O}$  and  $T$ , linked to the defect chemistry interpretation, allows the applicability of  $\text{Ba}_2\text{In}_{2-x}\text{S}_x\text{O}_{5.6}$  as an active material in intermediate temperature SOFCs and other electrochemical devices to be assessed.

## 2. Experimental Procedure

$\text{Ba}_2\text{In}_{1.8}\text{S}_{0.2}\text{O}_{5.3}$  was prepared by solid-state reaction in a similar process to that previously described<sup>24</sup>. Stoichiometric amounts of high purity reagents,  $\text{BaCO}_3$  (Aldrich, 99.98%),  $\text{In}_2\text{O}_3$  (Aldrich, 99.99%) and  $(\text{NH}_4)_2\text{SO}_4$  (Fluka, >98%) were weighed and, subsequently mixed in a mortar and pestle; a 3% excess of  $\text{BaCO}_3$  was added to compensate for possible Ba losses under high temperature sintering<sup>28</sup>. The sample was then pelletized, heated at 1000 °C for 12 h (5 °C min<sup>−1</sup> ramp rate) and cooled down to room temperature (RT). After crushing and homogenization, resulting powders were ball-milled at 250 rpm for 2 h (planetary ball mill PM200, Retsch) using  $\text{ZrO}_2$  vessel and balls. Powders were again pelletized, heated at 1000 °C for 50 h and cooled down to RT (5 °C min<sup>−1</sup> heating/cooling ramp rate).

The phase purity of the pale yellow colour samples obtained was analyzed by powder X-ray diffraction (XRD) using Bruker D8 high-resolution diffractometer equipped with a position sensitive detector (PSD) MBraun PSD-50M, with a monochromatic  $\text{CuK}\alpha_1$  ( $\lambda = 1.5406$  Å) radiation obtained with a germanium primary monochromator. Diffraction patterns were analyzed by Le Bail fitting using the FullProf software<sup>29</sup> in the  $2\theta = 10$ – $140^\circ$  angular range.

Scanning electron microscopy (SEM) were performed with a FEI XL30<sup>®</sup> system (4000 magnification) equipped with an EDAX<sup>®</sup> analyser for energy dispersive spectroscopy (EDS).

The experimental specimens for impedance spectroscopy (IS) were prepared by ball-milling (350 rpm for 1 h) the heated samples, isostatic pressing in cylindrical die (200 MPa,  $\approx 12$  mm diameter) and sintering at 1300 °C for 6 h (heating and cooling rates of 2 °C min<sup>−1</sup>) to yield pellets of  $\approx 10$  mm diameter and  $\approx 2$  mm thick. The as-obtained samples exhibited closed porosity and a relative density  $\sim 90$  %. Platinum paste was painted on each side of the pellets and fired at 900 °C for 2 h to yield the contact electrodes. IS measurements were performed with a PGSTAT302N Autolab (Ecochemie) by applying AC signal with an amplitude of 50 mV in the frequency range 0.1– $10^6$  Hz and measured in the direction of decreasing temperature over the 850–350 °C temperature interval (50 °C step<sup>−1</sup>). The experimental procedure was applied to dry/wet  $\text{N}_2$  and  $\text{O}_2$  atmospheres. Humid conditions were obtained by bubbling gases through room temperature KCl saturated distilled water in a thermostatic flask. Dry conditions were obtained using a Varian moisture gas clean filter. Repeated impedance measurements were recorded to confirm the equilibrium of the system. ZView software (Scribner Associates) was used to analyze the impedance spectra.

EMF measurements were carried out in a controlled atmosphere device similar to that previously described<sup>30</sup>. A sintered pellet of  $\text{Ba}_2\text{In}_{1.8}\text{S}_{0.2}\text{O}_{5.6}$  was hermetically sealed onto a YSZ sensor tube which was introduced into a closed alumina tube. Each chamber of the cell was equilibrated in selected atmospheres by flowing different gas mixtures in the 500–800 °C temperature range (50 °C step<sup>−1</sup>). The oxidizing conditions of the gas mixtures were obtained by selecting different  $\text{O}_2/\text{N}_2$  rates while various levels of humidity were achieved by mixing different proportions of wet and dry atmospheres<sup>31</sup>. To avoid the thermovoltage contribution, voltage measures were corrected by inverting the gas compositions present in each chamber (thereby, inverting the chemical potential gradient), allowing the offset potential to be eliminated from the measured voltages<sup>31</sup>. The effect of electrode polarization on the measured values of electromotive force of the system was taken into account by an active load modification of the methodology. For this purpose the electromotive force was monitored as a function of a variable external resistance located in parallel to the system, as previously reported<sup>32, 33</sup>. Voltage measurements were collected for different values of resistances using a Fluke 45 digital multimeter.

## 3. Results and discussion

### 3.1 Structural analysis

The X-ray powder diffraction pattern of  $\text{Ba}_2\text{In}_{1.8}\text{S}_{0.2}\text{O}_{5.6}$  showed a pure phase material without any secondary phases. The pattern was fully indexed by LeBail refinement (Figure 1) in the orthorhombic system (S.G. *Icmm* #74) to give lattice parameters of  $a = 5.9739(2)$ ,  $b = 16.9978(6)$  and  $c = 6.0477(3)$  Å, which result in a cell volume of  $614.10$  Å<sup>3</sup>, in close

agreement to that previously reported<sup>25</sup>. The current results, thereby, reinforce the work of Shin et al.<sup>25</sup> to show that introduction of sulfur in the Ba<sub>2</sub>In<sub>2</sub>O<sub>5+δ</sub> structure promotes oxygen sublattice disorder and formation of the perovskite phase.

Figure 1. Observed (red points), calculated (solid black line) and difference (blue line at the bottom) patterns for the LeBail refinement of Ba<sub>2</sub>In<sub>1.8</sub>S<sub>0.2</sub>O<sub>5.6</sub> diffraction pattern. The vertical green bars indicate the peak positions of all allowed Bragg reflections for *Icmmm* S. G.

3.2 Microstructure

Figure 2 displays SEM analyses of the Ba<sub>2</sub>In<sub>1.8</sub>S<sub>0.2</sub>O<sub>5+δ</sub> ceramic pellet. The back-scattered electron (BSE) image in Fig. 2(a) suggests high homogeneity and no segregation or secondary phases, showing very uniform contrast colours. Energy Dispersive X-ray spectroscopy (EDS) confirms Ba<sub>2</sub>In<sub>1.8</sub>S<sub>0.2</sub>O<sub>5+δ</sub> as single phase and table 1 shows that the experimental chemical composition is in agreement to the expected nominal stoichiometry. The elemental distribution of EDS maps (Fig. 2(b-e)) show good sample homogeneity, reinforcing the absence of secondary phases.

Figure 2. SEM micrographs of Ba<sub>2</sub>In<sub>1.8</sub>S<sub>0.2</sub>O<sub>5+δ</sub> at x4000 magnification factor: a) Back-scattered electrons (BSE) image and corresponding topographic view, and b), c), d) and e) correspond to Ba, O, In and S elemental distribution maps.

Table 1. Nominal and experimental chemical compositions (as determined by EDS) of Ba<sub>2</sub>In<sub>1.8</sub>S<sub>0.2</sub>O<sub>5+δ</sub>.

Description	Nominal	Sintered sample
Ba / In	1.11	1.13(2)
In / S	9.00	8.50(2)
Ba / S	10.00	9.63(1)

3.3 Electrical transport properties of Ba<sub>2</sub>In<sub>1.8</sub>S<sub>0.2</sub>O<sub>5+δ</sub>

The electrical conductivity of Ba<sub>2</sub>In<sub>1.8</sub>S<sub>0.2</sub>O<sub>5+δ</sub> was studied as a function of temperature in dry/wet N<sub>2</sub> and O<sub>2</sub> atmospheres by electrochemical impedance spectroscopy (IS) by deconvolution of the contributions ascribed to the bulk, grain boundary and electrode responses.

Figure 3 shows some examples of impedance spectra at 408 °C for dry/wet O<sub>2</sub> and N<sub>2</sub>, where substantial differences can be identified according to the different oxidising/wetting characters of the atmospheres, suggesting contribution of different species to the electrical transport. In wet O<sub>2</sub>, the impedance spectrum shows a predominant arc for frequencies lower than 10<sup>4</sup> Hz with a prevalent capacitive contribution of 10<sup>-3</sup> F, attributable to the polarisation processes at the electrodes. The electrolyte contribution to the overall transport is displayed as a shift of the spectrum in the real axis. Also, an inductive tail ascribed to the overall setup arises at higher frequencies. On the contrary, the spectrum under dry O<sub>2</sub> is dominated by a high frequency contribution ascribed to the transport through the electrolyte and a minor low-frequency arc associated to the electrode polarization process. These features point not only to a higher resistance under dry atmospheres, but also suggest a higher contribution to the overall conductivity from electronic species. Broadly speaking, similar behaviours are observed under N<sub>2</sub> atmospheres, with higher resistances of the electrolyte contribution in comparison to the O<sub>2</sub> atmospheres.

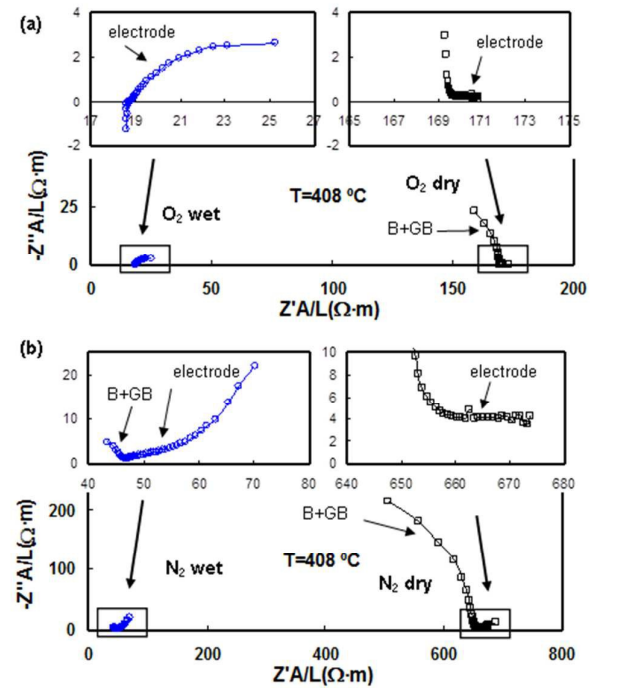

Figure 3. Impedance spectra obtained at 408 °C under dry/wet conditions of O<sub>2</sub> (a) and N<sub>2</sub> (b).

## ARTICLE

## Journal Name

In ceramic-protonic conductors, protons are incorporated in the lattice under wet conditions according to the hydration reaction:<sup>2, 34</sup>

where the equilibrium constant,  $K_\text{w}$ , could be approximated as:

$$K_\text{w} \approx \frac{[\text{OH}_\text{O}^{\bullet}]^2}{p\text{H}_2\text{O} \cdot [\text{V}_\text{O}^{\bullet\bullet}]} \quad (2)$$

On the other hand, under oxidising conditions, the oxygen vacancies are also in equilibrium with electronic holes by means of the oxygen gaseous species according to:

The mass action law of Eq. 3 could be approximately expressed as:

$$K_\text{O} \approx \frac{[\text{h}^{\bullet}]^2}{p\text{O}_2^{1/2} \cdot [\text{V}_\text{O}^{\bullet\bullet}]} \quad (4)$$

According to Eqs. 1-4, the concentration of oxygen vacancies, protons and holes is directly dependent on  $p\text{O}_2$ ,  $p\text{H}_2\text{O}$  and  $T$ . The electroneutrality law for charged species in wet environments is expressed as follows:

$$2[\text{S}_\text{B}^{\bullet\bullet}] + 2[\text{V}_\text{O}^{\bullet\bullet}] + [\text{OH}_\text{O}^{\bullet}] + [\text{h}^{\bullet}] = [\text{In}_\text{B}'] \quad (5)$$

where the presence of  $\text{In}^{3+}$  and  $\text{S}^{6+}$  in the B position of the perovskite should be counterbalanced by the rest of charged defects.

The temperature dependence of conductivity under several gas conditions is shown in Fig. 4. The results in dry gases show an improvement in conductivity under the more oxidising character of  $\text{O}_2$  gas in comparison to  $\text{N}_2$  gas, which suggests that hole species affect the overall electrical transport, according to Eqs. 3-4. The activation energy is  $\sim 0.85$  eV in the whole range of temperature for dry conditions of both  $\text{O}_2$  and  $\text{N}_2$ , in agreement with that expected for this contribution<sup>35</sup>. Under humid atmospheres, an enhancement of conductivity is apparent between 350-550 °C, in comparison to dry conditions, for both gases. This is a clear indication that protonic species are involved in the overall conduction. The activation energy in wet environments is  $\sim 0.34$ - $0.39$  eV, in the aforementioned temperature range. The measured value of activation energy is a consequence of the different conduction processes associated with the various species. In the current case its value points to protons as the prevalent carriers<sup>2, 7, 10</sup>. The measured activation energy rises for temperatures higher than 550 °C and the values of conductivity approach those obtained under dry conditions. The exothermic enthalpy of Eq. 1 implies that the concentration of protons would decrease for

higher temperatures<sup>2</sup>. This phenomenon supports the minor contribution of protonic species in this range, which leaves oxygen vacancies and electron holes as the main electrical carriers. The conductivity values offered by the  $\text{Ba}_2\text{In}_{1.8}\text{S}_{0.2}\text{O}_{5+\delta}$  material in Fig.4 are higher than that shown for the base  $\text{Ba}_2\text{In}_2\text{O}_5$  material in the literature<sup>10, 24</sup>, underscoring the beneficial nature of oxygen disorder upon sulfur(VI) doping.

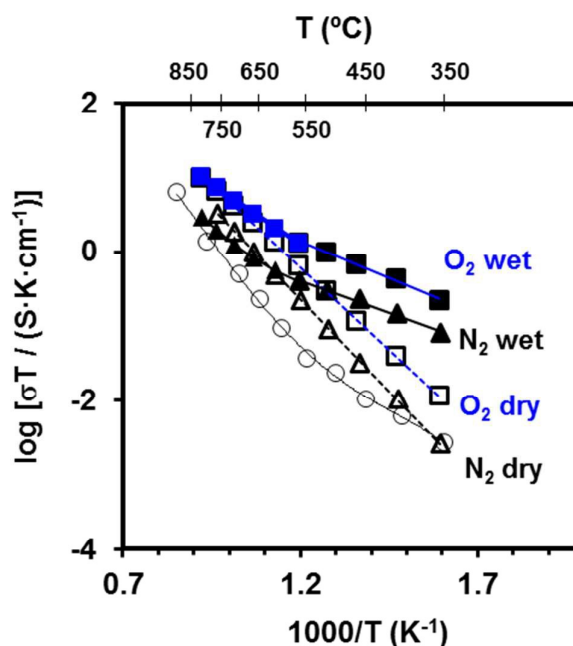

Figure 4. Temperature dependence of conductivity in wet and dry conditions of  $\text{N}_2$  and  $\text{O}_2$ . A value of  $p\text{H}_2\text{O} \approx 0.023$  atm was employed under wet conditions. Open circles represent literature conductivity data of  $\text{Ba}_2\text{In}_2\text{O}_5$  in wet air<sup>10</sup>

The specific conductivity of the various carriers under wet and dry conditions was obtained by means of a modified emf methodology in the range 500-800 °C.

For determination of the protonic conductivity under wet conditions, each side of the sample (sealed onto an YSZ tube) was submitted to the same  $\text{N}_2/\text{O}_2$  mixture of 41.25/8.75  $\text{ml}\cdot\text{min}^{-1}/\text{ml}\cdot\text{min}^{-1}$ , which produces the same value of  $p\text{O}_2 \approx 0.175$  atm in both compartments. Simultaneously, a gradient of  $p\text{H}_2\text{O}$  was established by exposing each gas flow to different levels of humidification controlled by mixing wet and dry gas fractions. A  $p\text{H}_2\text{O}$  ratio of  $\sim 5.75 \times 10^{-3} / 2.3 \times 10^{-3}$  atm/atm was selected during the experiment for this aim. Under these conditions, an auxiliary-variable resistance located in parallel to the sample produces a modification of the measured electromotive force of the system ( $E_\text{M}$ ) according to<sup>32, 33</sup>.

$$(\text{E}_{\text{H}_2\text{O}} \cdot \text{E}_\text{M}^{-1}) - 1 = (\text{R}_\text{H} + \text{R}_\text{H})\text{R}_\text{M}^{-1} + (\text{R}_\text{e}^{-1} + \text{R}_\text{O}^{-1})(\text{R}_\text{H} + \text{R}_\text{H}) \quad (6)$$

where  $R_H$ ,  $R_e$  and  $R_O$  correspond to protonic, electronic and oxide-ionic resistances, respectively;  $R_M$  is the auxiliary-variable resistance;  $R_\eta$  is the electrode-polarization resistance associated to the electrochemical reaction during the permeation process, and  $E_{H_2O}$  corresponds to the Nernst voltage associated to the present  $pH_2O$  gradient, determined by:

$$E_{H_2O} = -\frac{RT}{2F} \ln \left( \frac{pH_2O'}{pH_2O''} \right) \quad (7)$$

Equation 6 shows that the factor  $[(E_{H_2O} \cdot E_M^{-1}) - 1]$  presents a linear behaviour as a function of the variable  $R_M^{-1}$ . It follows that the protonic conductivity under the present working conditions can be determined by:

$$\sigma_H = \sigma_T - (\sigma_O + \sigma_e) = [R_T^{-1} - (R_O^{-1} + R_e^{-1})] \frac{L}{A} \quad (8)$$

where the factor  $(R_O^{-1} + R_e^{-1})$  is determined by the intercept over the slope of the linear representation of Eq. 6 and  $R_T$  is the total resistance of the sample, which is determined independently by impedance spectroscopy at the same working conditions.

For the determination of electronic and oxide-ionic conductivities, the average values of  $pO_2$  and  $pH_2O$  were maintained as the same of the first experiment. In this situation, it is considered that the transport properties are imposed by the average working conditions through the sample. Therefore, a  $pO_2$  gradient of 0.25/0.1 atm/atm was created across the sample by applying a mixture of 12.5  $ml \cdot min^{-1}$  of  $O_2$  and 37.5  $ml \cdot min^{-1}$  of  $N_2$  to one compartment and 5  $ml \cdot min^{-1}$  of  $O_2$  with 45  $ml \cdot min^{-1}$  of  $N_2$  to the other compartment. Both mixtures were hydrated to produce the same  $pH_2O \approx 4.025 \times 10^{-3}$  atm in both chambers. The implementation of an external-variable resistance modifies the measured value of emf according to<sup>33</sup>:

$$(E_{O_2} \cdot E_M^{-1}) - 1 = C \cdot R_M^{-1} + C \cdot R_e^{-1} \quad (9)$$

Where  $C$  is a constant value that depends on the protonic resistance and oxide-ionic resistance of the sample and the polarisation resistance of the electrodes, and  $E_{O_2}$  is the Nernst voltage associated to the  $pO_2$  gradient, according to:

$$E_{O_2} = \frac{RT}{4F} \ln \left( \frac{pO_2'}{pO_2''} \right) \quad (10)$$

From Eq. 9 it follows that the value  $R_e^{-1}$  could be determined from the intercept over the slope of the linear representation of  $[(E_{O_2} \cdot E_M^{-1}) - 1]$  vs.  $R_M^{-1}$ . Thus, the electronic- and oxide-ionic conductivities could be obtained according to the expressions presented below:

$$\sigma_e = R_e^{-1} \frac{L}{A} \quad (11)$$

$$\begin{aligned} \sigma_O &= \sigma_T - (\sigma_H + \sigma_e) = [R_T^{-1} - (R_H^{-1} + R_e^{-1})] \frac{L}{A} \\ &= [(R_O^{-1} + R_e^{-1}) - R_e^{-1}] \frac{L}{A} \end{aligned} \quad (12)$$

Note that the values  $(R_O^{-1} + R_e^{-1})$  and  $R_e^{-1}$  are directly obtained from the described experiments.

Fig. 5 shows an example of the dependence of  $E_M$  as a function of  $R_M^{-1}$  at 650 °C under the  $pH_2O$  gradient and the constant  $pO_2$  indicated above in the first experiment. A very good fit between the experimental data and a linear behaviour is apparent, supporting the methodology. The complementary experiment with a  $pO_2$  gradient and constant  $pH_2O$  was then accomplished to determine the electrical conductivities associated to the various species. This procedure was repeated at each temperature in the range 500-800 °C, and the results are shown in Fig. 6 for dry and wet conditions. For dry conditions, a specific situation of the second experiment with a  $pO_2$  gradient arises, where it is assumed that the material possesses an insignificant content of protonic species. Therefore, Eqs. 9-12 are also shown to be valid, with the particularity of  $R_H^{-1} \approx 0$ .

Figure 5. Linear dependence of the measured emf of the sample with the variable auxiliary resistance. Note that  $E_M$  is the measured value of emf,  $E_{H_2O}$  is the Nernst value associated with the same gradient of  $pH_2O$  and  $R_M$  is the corresponding value of the auxiliary resistance that produces the modification of the experimental emf.

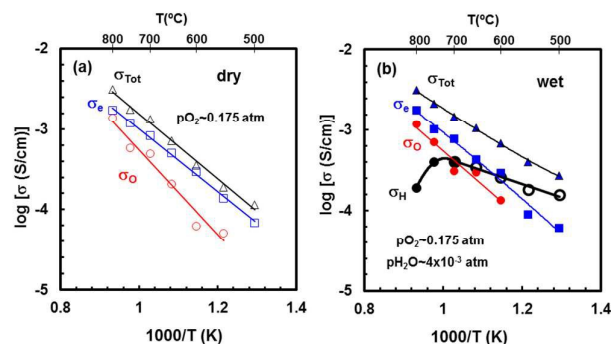

Figure 6. Temperature dependence of the conductivity associated to different species in dry (a) and wet (b) conditions.

Fig. 6(a) shows that the sample possesses a mixed oxide-ionic/electronic behaviour in dry conditions, due to the prevalent equilibrium between the oxygen vacancies and electron holes in oxidising atmospheres (Eq. 3). On the other hand, under humid atmospheres, a protonic component emerges, with a positive impact on the overall transport, mainly for temperatures lower than 700 °C, and governing the electrical conductivity for  $T \leq 550$  °C. The exothermic character of the hydration reaction (Eq. 1) reduces the concentration of protons as temperature rises, which leads to a maximum in protonic conductivity at about 700-750 °C, decreasing for higher temperatures, despite an improved mobility. As a consequence, the electrical conductivity is practically identical in both wet and dry atmospheres for  $T \geq 800$  °C (Figs. 4 and 6).

Figure 7. Experimental results of conductivity (closed circles) as a function of  $pH_2O$  in  $N_2$  atmosphere (a) and as a function of  $pO_2$  for a fixed value of  $pH_2O \approx 0.023$  atm. Estimations of conductivity associated to different charge carriers (lines) are also presented.

The effect of working conditions on the transport properties was also analysed by changing the wet/dry dilution ratio and/or the oxidising character of the atmosphere. Fig. 7 shows the total conductivity obtained by impedance spectroscopy in a symmetric atmosphere of  $N_2$  as a function of  $pH_2O$  (Fig. 7(a)) and as a function of  $pO_2$ , using wet mixtures of  $N_2/O_2$ , for a fixed value of  $pH_2O \approx 0.023$  atm (Fig. 7(b)). The experimental results were contrasted with the estimated behaviour according to the defect chemistry. For this purpose, the concentration of protons and holes were expressed as a

function of the oxygen vacancy concentration by means of Eqs. 2 and 4. This was combined with the electroneutrality law (Eq. 5), resulting in a 2-order-polynomial equation, which is analytically solved to obtain the concentration of the different species for the desired range of  $pO_2$  and  $pH_2O$  (Fig. 8)<sup>36</sup> (note that the determination of  $pO_2$  in  $N_2$  atmosphere was performed by means of a YSZ- $pO_2$  sensor). Table 2 shows the values of equilibrium constants and mobility ratios between different carriers used to obtain the estimations of defect profiles and conductivities. Some values extracted from literature for other perovskite systems are also shown for comparison<sup>37-41</sup>. Fig. 8(a) shows that the concentration of holes as a function of  $pO_2$  in wet  $N_2$  is practically constant. We should note here that the use of  $N_2$  produces a slight increase of  $pO_2$  for higher  $pH_2O$ . This produces the effect that the hole-concentration profile is slightly altered in comparison to that which would be obtained for a fixed value of  $pO_2$ . A slight decrease in hole concentration should, thus, be obtained as  $pH_2O$  rises under these conditions. On the other hand, Fig. 8(a) shows that the concentration of ionic species is at least three orders of magnitude higher than that of electronic carriers, with predominance of oxygen vacancies in drier conditions and protons in wetter conditions. The increase of  $pO_2$  in the latter situation has the effect to increase the concentration of holes with a  $1/4$ -power law dependence (Eq. 4), keeping both the concentration of protons and oxygen vacancies as constants (Fig. 8(b)). The introduction of the expected mobilities of the various carriers allows the fitting of experimental data with those obtained from the defect chemistry. Although the latter results are only estimations, they fit well with the experimental values. It is noteworthy that both graphs in Fig. 7 were fitted simultaneously with the same parameters (equilibrium constants and mobilities) to support the methodology.

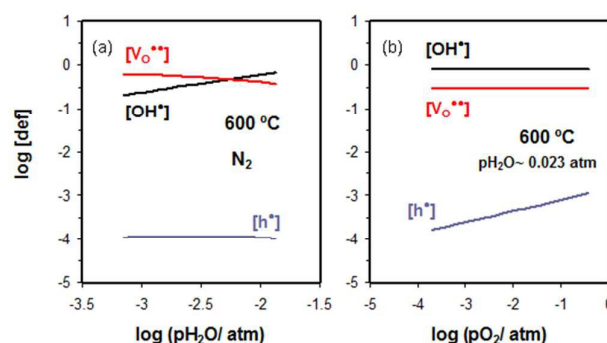

Figure 8. Estimations of defect profiles associated to different carriers, according to the defect chemistry, as a function of  $pH_2O$  in  $N_2$  atmosphere (a) and as a function of  $pO_2$  for mixtures of  $N_2/O_2$  in wet conditions.

According to the literature (Table 2) it is expected that the mobility of protons is several times higher than that of oxygen vacancies and the hole mobility should be at least two orders of magnitude higher than that of ionic species. As a consequence, under  $N_2$  atmosphere (Fig. 7(a)), the total conductivity seems not to be affected by electronic holes,

whereas protons dominate the overall transport at higher humidities and oxygen vacancies have some influence for drier conditions. Conversely, an increase in  $pO_2$  at the highest humidities ( $pH_2O \approx 0.023$  atm), produces a mixed-conducting behaviour with a raised contribution of the electronic component (Fig. 7(b)), despite its lower charge carrier concentration (Fig. 8(b)). These results highlight the possibility

of tuning the mixed transport properties of the studied sulfur-doped  $Ba_2In_2O_{5+\delta}$  material by selection of the appropriate environmental conditions, pointing to a wide range of possibilities in intermediate temperature electrochemical applications, such as the electrochemical promotion of chemical reactions<sup>42, 43</sup>, membrane reactors<sup>44</sup> and also fuel cells<sup>45</sup>.

Table 2. Equilibrium constants and mobility ratios between different charge carriers employed in the simulation of defect profiles and conductivities by means of the defect chemistry. Some values extracted from literature for other perovskite systems are also shown for comparison.

4. Conclusions

A disordered orthorhombic perovskite was successfully synthesised by the introduction of a sulfur content of  $x=0.2$  in  $Ba_2In_{2-x}S_xO_{5+\delta}$ . The overall electrical conductivity of the obtained composition is considerably enhanced in comparison to literature data on the undoped sample, related to the improved disorder of the oxygen sublattice. Different charge species were found as dominant electrical carriers on the variation of the environmental conditions such as temperature, oxygen partial pressure and water partial pressure. In dry oxidising atmospheres, the electrical behaviour is dominated by both oxide-ions and hole carriers, due to the equilibrium between oxygen vacancies and holes under conditions of high  $pO_2$ . Under humid environments the hydration reaction occurs and protonic species arise at the expense of oxygen vacancies. Protonic carriers control the overall electrical transport for temperatures lower than 550 °C, while having an insignificant contribution at temperatures higher than 750 °C. A mixed contribution from protons, oxide ions and holes is apparent between 550-700 °C, pointing to interesting applications for intermediate temperature devices, such as electrochemical membranes.
